Bloom Filter Overview

Application example: Program for automatic hyphenation in which 90% of words can be hyphenated using simple rules, and 10% require dictionary lookup.
Bloom Filter Principle

“Whenever a list or set is used, and space is consideration, a Bloom filter should be considered. When using a Bloom filter, consider the potential effects of false positives.”
Notation

$S$ is a set of $n$ elements.

Set of $k$ hash functions with range $\{1 \ldots m\}$ (or $\{0 \ldots m - 1\}$).

$m$-long array of bits initialized to 0.
Families of Hash Functions

$k$ hash functions $h_1 \ldots h_k$

We could use SHA1, MD5, etc.

How could we get a family of size $k$?

$h_i(x) = \text{MD5}(x + i)$ or $\text{MD5}(x \parallel i)$ would work.
Example

We insert and query on a Bloom filter of size $m = 10$ and number of hash functions $k = 3$.

Let $H(x)$ denote the result of the three hash functions which we will write as a set of three values \{h_1(x), h_2(x), h_3(x)\}

We start with an empty 10-bit long array:

<table>
<thead>
<tr>
<th>0</th>
<th>1</th>
<th>2</th>
<th>3</th>
<th>4</th>
<th>5</th>
<th>6</th>
<th>7</th>
<th>8</th>
<th>9</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>0</td>
<td>0</td>
<td>0</td>
<td>0</td>
<td>0</td>
<td>0</td>
<td>0</td>
<td>0</td>
<td>0</td>
</tr>
</tbody>
</table>
Insert $x_0$:

$H(x_0) = \{1, 4, 9\}$

\[
\begin{array}{cccccccccc}
0 & 1 & 2 & 3 & 4 & 5 & 6 & 7 & 8 & 9 \\
0 & 1 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 1
\end{array}
\]

Insert $x_1$:

$H(x_1) = \{4, 5, 8\}$

\[
\begin{array}{cccccccccc}
0 & 1 & 2 & 3 & 4 & 5 & 6 & 7 & 8 & 9 \\
0 & 1 & 0 & 0 & 1 & 1 & 0 & 0 & 1 & 1
\end{array}
\]
$H(x_0) = \{1, 4, 9\}$

$H(x_1) = \{4, 5, 8\}$

<table>
<thead>
<tr>
<th>0</th>
<th>1</th>
<th>2</th>
<th>3</th>
<th>4</th>
<th>5</th>
<th>6</th>
<th>7</th>
<th>8</th>
<th>9</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>1</td>
<td>0</td>
<td>0</td>
<td>1</td>
<td>1</td>
<td>0</td>
<td>0</td>
<td>1</td>
<td>1</td>
</tr>
</tbody>
</table>

Query $y_0$:

$H(y_0) = \{0, 4, 8\} \rightarrow \text{No}$

Query $y_1$:

$H(y_1) = \{1, 5, 8\} \rightarrow \text{Yes (False Positive)}$
A Little Math (Broder & Mitzenmacher)

After $n$ elements inserted into bloom filter of size $m$, probability that a specific bit is still 0 is

$$\left(1 - \frac{1}{m}\right)^{kn} \approx e^{-\frac{kn}{m}}$$

(The useful approximation comes from a well-known formula for calculating $e$):

$$\lim_{x \to \infty} \left(1 - \frac{1}{x}\right)^{-x} = e$$

Thus the probability that a specific bit has been flipped to 1 is

$$1 - \left(1 - \frac{1}{m}\right)^{kn} \approx 1 - e^{-\frac{kn}{m}}$$
Useful Approximation

<table>
<thead>
<tr>
<th>$x$</th>
<th>$(1 - \frac{1}{x})^{-x}$</th>

<td>2.718287</td>
</tr>
<tr>
<td>1048576</td>
<td>2.718283</td>
</tr>
<tr>
<td>4194304</td>
<td>2.718282</td>
</tr>
</tbody>
</table>
A Little Math

A false positive on a query of element $x$ occurs when \textbf{all} of the hash functions $h_1 \ldots h_k$ applied to $x$ return a filter position that has a 1.

We assume hash functions to be \textit{independent}.

Thus the probability of a false positive is

$$f = \left(1 - \left(1 - \frac{1}{m}\right)^{kn}\right)^k \approx \left(1 - e^{-\frac{kn}{m}}\right)^k$$
Choose $k$ To Minimize False Positives

We are given $m$ and $n$, so we choose a $k$ to minimize the false positive rate.

Let $p = e^{\frac{-kn}{m}}$. Thus we have

\[
f = \left(1 - e^{\frac{-kn}{m}}\right)^k = (1 - p)^k = e^{k \ln(1-p)}
\]

So we wish to minimize $g = k \ln (1 - p)$. 
Choose $k$ To Minimize False Positives

We could use calculus. Less messy, we notice that since

$$\ln \left( e^{-\frac{kn}{m}} \right) = -\frac{kn}{m}$$

we have

$$g = k \ln (1 - p) = -\frac{m}{n} \ln (p) \ln (1 - p)$$

and by symmetry, we see that $g$ is minimized when $p = \frac{1}{2}$
Choose $k$ To Minimize False Positives

Since $p = e^{-\frac{kn}{m}}$, when $p = \frac{1}{2}$ we have

$$k = \ln 2 \cdot \left( \frac{m}{n} \right)$$

Plugging back into $f = (1 - p)^k$, we find the minimum false positive rate is

$$\left( \frac{1}{2} \right)^k \approx (.6185)^{\frac{m}{n}}$$

Caveat: $k$ must be an integer.
Optimal Filter Structure

Recall $p = e^{-\frac{kn}{m}}$ is the probability that any specific bit is still 0.

So $p = \frac{1}{2}$ corresponds to a half-full Bloom filter array.

Outline

- Bloom Filter Overview

- Traditional Applications

- Hierarchical Bloom Filters Paper

- Less Traditional Applications & Extensions
Application: Weak Password Dictionary

Store dictionary of easily guessable passwords as bloom filter, query when users pick passwords.

Can add new entries (e.g. previously used passwords).
Application: Weak Password Dictionary

What is a false positive in this context?
Application: Weak Password Dictionary

What is a false positive in this context?

A strong password that happens to hit. No big deal, just ask user for another one.
Weak Password Dictionary Caveat

Normally, we don’t care about cryptographically strong hash functions.

But if we store sensitive data (previously used passwords), we do care, given attacker can see change in filter.

Solution: Use strong hash functions, or encrypt words before entering.
Application: Traceback

“Hash-Based IP Traceback”, A. Snoeren et al., SIGCOMM, 2001

Developed “Source Path Isolation Engine” (SPIE)

600.424 Week 5 (Oct 10) related reading, remember??????
SPIE Traceback

Different goal than HBF authors:

“In an IP framework, the packet is the smallest atomic unit of data. Any smaller division of data (a byte for instance) is contained within a unique packet. Hence an optimal IP traceback system would precisely identify the source of an arbitrary IP packet”.
SPIE Traceback

Hashes “invariant” fields of IP header and first 8 bytes of payload into Bloom filter.

Explicitly handles fragmentation, NAT, ICMP messages (?), IP-in-IP tunneling (?) and IPsec (?) using additional 64-bit data structure
<table>

</tr>
</tbody>
</table>

Payload

Figure 2: The fields of an IP packet. Fields in gray are masked out before digesting, including the Type of Service, Time to Live (TTL), IP checksum, and IP options fields.
SPIE Bloom Filter Usage

Each router in path hashes packet digests into Bloom filters which are paged and stored locally for some amount of time.

Key point: Each router’s hash functions are independent. They are based on RNG seeded at each router and changed every page out.

So false positives are independent of false positives at other routers or at other time periods.
Application: Cache Sharing

Proxies on same side of network bottleneck share their caches.

Proxies use Internet Cache Protocol (ICP). Messages sent out to all other proxies on cache misses.

Involves a lot of interproxy communication, adding to network load.
Application: Cache Sharing

Proxy hashes all of the URLs in its cache into Bloom Filter.

Proxies periodically exchange Bloom filters, so queries of other caches can be made locally without sending ICP message.
Application: Cache Sharing

Proxy hashes all of the URLs in its cache into Bloom Filter.

Proxies periodically exchange Bloom filters, so queries of other caches can be made **locally** without sending ICP message.

What’s a false positive? Is it a big deal?

What’s a false *negative*? Is it a big deal?
A

B

Nope!

WAN

40
False Positives / Negatives

False positive: Proxy A thinks Proxy B has URL U cached. A asks for cached U, B responds back with “no”, A goes to actual website.

False negative: Proxy A thinks nobody has URL U cached, so it goes directly to website.

Result: a little extra traffic.
Problem: Deleting Items

Proxies remove pages from their cache, so they need to remove items from the Bloom filter.

How do we do this?
No Deletion Support

Recall our example Bloom filter of two items:

\[ H(x_0) = \{1, 4, 9\} \]

\[ H(x_1) = \{4, 5, 8\} \]

Can’t delete one without clobbering the other since they share address 4.
No Deletion Support

Delete $x_0$:

$H(x_0) = \{1, 4, 9\}$

\[
\begin{array}{cccccccccc}
0 & 1 & 2 & 3 & 4 & 5 & 6 & 7 & 8 & 9 \\
0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 1 & 0 \\
\end{array}
\]

Query $x_1$:

$H(x_1) = \{4, 5, 8\} \rightarrow \text{No (False Negative)}$
Solution: Counting Filters?

In addition to storing bit at each address of filter, we store counter for each position.

Counter is incremented on insertion and decremented on deletion.

Bit in filter flipped when counter changes from 0 to 1 or 1 to 0.

In our example, we’d have the following counter array:

<table>
<thead>
<tr>
<th>0</th>
<th>1</th>
<th>2</th>
<th>3</th>
<th>4</th>
<th>5</th>
<th>6</th>
<th>7</th>
<th>8</th>
<th>9</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>1</td>
<td>0</td>
<td>0</td>
<td>2</td>
<td>1</td>
<td>0</td>
<td>0</td>
<td>1</td>
<td>1</td>
</tr>
</tbody>
</table>
Counting Filters Issues

Counter Overflow? No chance! (kind of)

- Authors propose 4-bit counters enough

- In technical paper, with lots of math, show with 4-bit counters and \( k < \ln 2 \cdot \left( \frac{m}{n} \right) \), probability of overflow

  \[ \leq 1.37 \times 10^{-15} \times m \]

- If counter overflows, just keep it at max value
Counting Filters: More Generally

What if we insert and delete multiple copies of the same item into a counting Bloom Filter? Can we reliably count the instances of items in the filter?
Counting Filters: More Generally

What if we insert multiple copies of the same item into a Bloom Filter? Can we use counting filters to count the instances of items in the filter? **NO!**

We insert $\geq 16$ times and delete 15 times, and have a resulting **false negative**.

Recall: Summary Cache authors don't care so much about false negatives anyway.

We'll see a cooler use of Bloom Filters as counters later.
Outline

- Bloom Filter Overview
- Traditional Applications
- Hierarchical Bloom Filters Paper
- Less Traditional Applications & Extensions
Hierarchical Bloom Filters

Use Bloom Filter extension to store portions of packets for the purposes of payload attribution.

While SPIE is “packet digesting scheme”, their proposal is a “payload digesting scheme”.

Applications

- We possess piece of virus, shellcode, etc., and want to see if it was in any packets.
  
  - “Fornet: A Distributed Forensics Network”

- Track unauthorized disclosure of sensitive information from own network.
First Critique: Bad \LaTeX

Variables typeset like these are lame: $offset$, $loffset$
BBFs

To support substring matching in Bloom filters, the Block-Based Bloom Filter (BBF) is introduced.

Payloads are broken into blocks of size $s$.

Blocks are inserted along with their offset in payload: (content||offset).
**BBF example from paper**

<table>
<thead>
<tr>
<th></th>
<th>0</th>
<th>1</th>
<th>2</th>
<th>3</th>
<th>4</th>
<th>5</th>
<th>6</th>
</tr>
</thead>
<tbody>
<tr>
<td>ABR</td>
<td>ACA</td>
<td>DAB</td>
<td>RAC</td>
<td>ADA</td>
<td>RAC</td>
<td>ABA</td>
<td></td>
</tr>
</tbody>
</table>

We query BRACADAB, giving three alignments of 2 blocks each

- **BRA CAD**: not found

- **ACA DAB**: found at offset 1

- **RAC ADA**: found at offset 3, half at 5

? “double false positive of the BBF” at offset 2 for RAC ADA ?
BBF Drawback

Two packets made up of blocks $S_0S_1S_2S_3S_4$ and $S_0S_2S_3S_1S_4$.

Query for $S_2S_1$ would be a false hit.
HBF example

\[
\begin{array}{c|c|c|c}
S_0S_1S_2S_3 & 0 \\
\hline
S_0S_1 & 0 & S_2S_3 & 1 \\
\hline
S_0 & 0 & S_1 & 1 & S_2 & 2 & S_3 & 3
\end{array}
\]

We get additional check to limit false positives when searching for multiblock strings.
HBF: Small string drawbacks

For some small strings we still appear to have BBF style false hit:

|          | $S_0S_1S_2S_3|0$ | $S_0S_1|0$ | $S_2S_3|1$ |
|----------|----------------|------------|------------|
| $S_0|0$   | $S_1|1$         | $S_2|2$     | $S_3|3$     |

|          | $S_0S_2S_3S_1|0$ | $S_0S_2|0$ | $S_3S_1|1$ |
|----------|----------------|------------|------------|
| $S_0|0$   | $S_2|1$         | $S_3|2$     | $S_1|3$     |

We still get false hit on $S_1S_3$ since hierarchy doesn’t capture two-block strings at odd offsets.
Several HBFs Used to make Payload Attribution System

- **Block Digest** (optional): hashes of (content) only

- **Offset Digest**: hashes of (content||offset). This is what was described above

- **Payload Digest**: hashes of (content||offset||hostID).
Attribution

- Destination Attribution: “not affected by spoofing”.
  - OK, but could get a lot of hits for internal worm/virus trying to propagate out of network

- Local Source Attribution: Can be accurate up to local subnet that HBF is in front of.
  - OK, I buy this
Attribution

- Foreign Source Attribution: Handwaves at using other forms of payload attribution that don’t rely on source IP address
  - For connection oriented sessions, claim is can trust source IPs.
  - It seems that they don’t really deal with spoofed source IPs: “...PAS suffers from denial of service attack as an attacker can overflow the list of host IDs used for full attribution”.
Attacks on PAS

● Splitting payload into packets smaller than blocksize
  – Could make PAS stateful

● Stuffing payload with \texttt{nops} or equivalent
  – HBFs make PAS more robust than packet digesting

● Some other less interesting issues are mentioned

Comments on HBF paper

Fairly simple construction for including varying length substrings in Bloom Filter.

Lots of handwaving about false positives.

Payload attribution not robust as long as it trusts source IPs.
Outline

- Bloom Filter Overview
- Traditional Applications
- Hierarchical Bloom Filters Paper
- Less Traditional Applications & Extensions
Using Bloom Filters to Measure Traffic Flow

We want to measure traffic flows. Flows can be defined by any combination of features, such as:

- IP address
- Ports
- Protocols
Measuring Flows

How can we measure both small and large traffic flows accurately?

- Counters? Does not scale for large flows and high link speeds.

- Random Sampling (like 1%)? Innaccurate, especially for small flows.
Space-Code Bloom Filters

Measure **approximate** sizes of flows.

Note: Assume flow information is unencrypted.

We extend Bloom Filters, accepting some false positives in favor of speed and memory savings.

Of course, we don’t use counting filters a la “Summary Cache”!
Space-Code Bloom Filters

Traditionally, we have set of hash functions $h_1, h_2, \ldots, h_k$

A SCBF has $l$ sets of $k$ hash functions

$$
\begin{align*}
&h^1_1, h^1_2, \ldots, h^1_k \\
&h^2_1, h^2_2, \ldots, h^2_k \\
&\vdots \\
&h^l_1, h^l_2, \ldots, h^l_k
\end{align*}
$$

When inserting element $x$, we choose one of $l$ sets at random and do normal BF insertion.
Space-Code Bloom Filters

When inserting element $x$, we choose one of $l$ sets at random.

When querying element $y$, we iterate through all $l$ sets of hash functions, and count number that hit, yielding multiplicity value $\hat{\theta}, 0 \leq \hat{\theta} \leq l$

We then use Maximum Likelihood Estimation (MLE) or Mean Value Estimation (MVE) to estimate multiplicity of $y$. 
Coupon Collector’s Problem

Given set of \( N \) elements, how many random samples do we expect before we hit all \( N \)?

Given that we’ve seen \( i \) elements, we will see a new element with probability \( \frac{N-i}{N} \). So we expect to need \( \frac{N}{N-i} \) samples before we get the \((i + 1)\)st element.

\[
\frac{N}{N} + \frac{N}{N-1} + \frac{N}{N-2} + \cdots + \frac{N}{1}
\]

\[
N \sum_{i=1}^{N} \frac{1}{i} \approx N \ln N
\]
How do we Choose $l$

We expect all $l$ sets of hash functions hit after $\approx l \ln l$ insertions of same element $x$.

For example $l = 32$, $l \ln l \approx 111$. So how do we differentiate 200 vs. 400 insertions?

Can’t make $l$ arbitrarily large
Solution: Use Many l’s: MRSCBF!

Multi-Resolution SCBF.

We use $r$ filters, each an SCBF. We associate probability of insertion into each filter $p_i$ where $p_1 > p_2 > \ldots > p_r$.

High $p_i$ are high-resolution filters, capture small flow information.

Low $p_i$ are low-resolution filters, capture large flow information.

Paper uses $l = 32$, $p_i = (0.25)^{(i-1)}$
MRSCBF querying

Given a flow identifier, we compute all $l$ functions on all $r$ filters, yielding the set of multiplicities $\tilde{\theta}_1, \tilde{\theta}_2, \ldots, \tilde{\theta}_r$.

Doing MVE or MLE is too computationally complex

So we use “most relevant” filters
Most Relevant Example

Let actual multiplicity of $x$ be 1000.

Filter at resolution 1 will have $\hat{\theta} = l$

Filter at resolution $\frac{1}{1024}$ will have $\hat{\theta}$ tiny, like 0 or 1

Probably best to use filter around $\frac{1}{16}$ or so.
Formalize Most Relevant Filter

If $x$ matches $\theta$ hash groups, it would take about $\frac{l}{l-\theta}$ to match another hash group.

The expected number of insertions given $\theta$ matches is

$$\left(\frac{l}{l} + \frac{l}{l-1} + \cdots + \frac{l}{l-\theta+1}\right)$$

Define *relative incremental inaccuracy* as

$$\frac{\frac{l}{l-\theta}}{\left(\frac{l}{l} + \frac{l}{l-1} + \cdots + \frac{l}{l-\theta+1}\right)}$$

and choose filter with smallest inaccuracy.
SCBF Takeaway

Very cool way of using Bloom filters as counters.

Addresses the problem of “Summary Cache” counting filters which couldn’t effectively deal with multiple copies of the same data item.
Fabian’s Extension: Privacy Preserving Observations

Interesting applications when many people have access to approximate counts of items.

Alice is interested in Bob’s count of item $X$, but doesn’t want to reveal her interest in $X$.

From Bob’s count of a different, uninteresting item $Y$ she can estimate his count of $X$.

So she asks for the count on $Y$ and then deduces an approximate count for $X$. 
Bloomier Filters

Associate a function value with $f$ with each element in domain $D$ of size $N$ such that:

- Range $R$ of $f$ is size $2^r = \{\bot, 1, \ldots, 2^r - 1\}$ where $\bot$ means undefined.

- Subset $S \subseteq D$ of size $n$ such that $f$ is defined for $x \in S$ and $f(x) = \bot$ for $x \notin S$
Bloomier Filters: More Concretely

Let $x_i$ be a set of elements separated into non-intersecting subsets $A_i$. For example:

\[
\begin{align*}
A_0 &= x_0, \ldots, x_9 \\
A_1 &= x_{10}, \ldots, x_{19} \\
A_2 &= x_{20}, \ldots, x_{29} \\
&\vdots
\end{align*}
\]

A Bloomier filter allows us to query an element $y$ and guarantees the correct subset $A_i$ if $y \in A_i$ for some $i$. If $y \notin A_i$ for all $i$, we should get $\bot$ unless we hit a false positive.
Extra Notation

Any element of range $R$ can be encoded as a $q$-bit binary number in the additive group $Q = \{0, 1\}^q$. It is important that $2^q > |R|$.

We still have $k$ hash functions $h_1, \ldots, h_k$ which return a value in range $1, \ldots, m$. In addition, we have one additional $q$-bit “masking value” $M$ returned by hashing.

We define the “neighborhood” $N(t)$ of $t \in S$ as the results of the $k$ hash functions, $\{h_1(t), \ldots, h_k(t)\}$

Let $\Pi$ be a total ordering on the elements of $S$. 
Immutable Table

The idea is to store $f(t)$ in the addresses of the table

$$\{h_1(t), \ldots, h_k(t)\}$$

such that

$$f(t) = M \oplus \bigoplus_{i=1}^{k} \text{Table}[h_i(t)]$$

The trick will be to figure out which address $h_i(t)$ to update for each element $t$ so that we don’t clobber another element’s stored value.
We’ll work through an example of creating an Immutable Bloom filter for the following parameters:

\[
\begin{align*}
  k & = 4 \\
  m & = 10 \\
  q & = 8 \\
  n & = 4 \\
  |R| & = 4
\end{align*}
\]

Where the range of \(f\) is the four values 0x11, 0x22, 0x44, 0x88

We will call the four elements of \(S\) \(\{A, B, C, D\}\)

Why do we Need $M$?

$M$, the “masking value” is used to eliminate false positives by effectively randomizing lookup misses.

We have $2^q > |R|$, so that $f(y) = \perp, y \notin S$ with probability $\frac{|R|}{2^q}$

Easy example: $0 \in R$, and we don’t use a mask $M$. With a table initialized to 0, lookups that hit addresses with no values (or values that sum to 0) would be false positives.
Why we Need $M$

<table>
<thead>
<tr>

<td>0x04</td>
<td>0x00</td>
<td>0x00</td>
</tr>
</tbody>
</table>

$R = \{0, 1, 2, 3, 4\}$

$N(y) = \{1, 4, 5, 9\}$ for $y \notin S$

$y$ is now a false positive.
“Mutable” Bloomier Filter

We use an extra table and one level of redirection so that we can update $f(t)$ for any $t \in S$.

Instead of storing $f(t)$ in the first table, we store the value $i \in \{1, \ldots, k\}$ for which $h_i(t) = \tau(t)$.

Then in second table, we store $f(t)$ in TABLE2 $[\tau(t)]$. 
So What’s the Catch?

There is (at least) one major downside to Bloomier filters. Did you catch it?
Major Downside of Bloomier Filters

“Mutable” Bloomier filter refers to being able to update $f(t)$ for $t \in S$. Membership in $S$ cannot change; the set $S$ itself is immutable.

- Must know entire set $S$ upon creation
- Cannot update filter with new elements after its creation

This would seem to severely limit its practical use.
Conclusions

Bloom Filters and their extensions are useful tools for a variety of applications in the field of security.

I happen to think HBFs are not among the coolest applications.

Again, the **Bloom Filter Principle**: “Whenever a list or set is used, and space is consideration, a Bloom filter should be considered. When using a Bloom filter, consider the potential effects of false positives.”
Matchings: More Notation

We say a matching $\tau$ respects $(S, \pi, N)$ if

- for all $t \in S$, $\tau(t) \in Nt$

- if $t_i > \pi t_j$ then $\tau(t_i) \notin N(t_j)$

In English, if we have $\tau(t)$ for all $t \in S$, then this gives an address in every element’s neighborhood for which we can update the table without clobbering any previously entered data!
Finding the Ordering $\Pi$ and Matching $\tau$

We say $h \in \{1 \ldots m\}$ is a *singleton* if $h \in N(t)$ for a unique $t \in S$.

We use the term $\text{TWEAK}(t, S, \text{HASH})$ to refer to the smallest singleton of $t$ (so that we have a defined one to pick in case $t$ has multiple singletons).

If every $t$ had a singleton, we’d be fine, we could use $\tau(t) = \text{TWEAK}(t, S, \text{HASH})$. 
Find Singletons Recursively

1. For all $t$ with a singleton, set $\tau(t) = \text{TWEAK}(t, S, \text{HASH})$.

2. Remove all these elements with singletons from $S$.

3. Put these elements in $\Pi$ after those still in $S$ but before those currently in $\Pi$.

4. Repeat until all elements are ordered. We fail if their are elements left with no singletons.
