Abstract
We present a generic fetch-and-$\phi$-based local-spin mutual exclusion algorithm, with $O(1)$ time complexity under the remote-memory-references time measure. This algorithm is “generic” in the sense that it can be implemented using any fetch-and-$\phi$ primitive of rank $2N$, where $N$ is the number of processes. The rank of a fetch-and-$\phi$ primitive is a notion introduced herein; informally, it expresses the extent to which processes may “order themselves” using that primitive. This algorithm breaks new ground because it shows that $O(1)$ time complexity is possible using a wide range of primitives. In addition, previously published fetch-and-$\phi$-based algorithms either use multiple primitives or require an underlying cache-coherence mechanism for spins to be local, while ours does not. By applying our generic algorithm within an arbitration tree, one can easily construct a $\Theta(\log r N)$ algorithm using any primitive of rank $r$, where $2 \leq r < N$. For primitives that meet a certain additional condition, we present a $\Theta(\log N/\log\log N)$ algorithm, which gives an asymptotic improvement in time complexity for primitives of rank $o(\log N)$. It follows from a previously-presented lower bound proof that this algorithm is asymptotically time-optimal for certain primitives of constant rank.

Keywords: Fetch-and-$\phi$ primitives, local spinning, shared-memory mutual exclusion, theory of concurrent algorithms, time complexity.

1 Introduction

Recent work on shared-memory mutual exclusion has focused on the design of algorithms that minimize contention for the processors-to-memory interconnection network through the use of local spinning. In local-spin algorithms, all busy waiting is by means of read-only loops in which one or more “spin variables” are repeatedly tested. Such spin variables must be either locally cacheable or stored in a local memory module that can be accessed without an interconnection network traversal. The former is possible on cache-coherent (CC) machines, while the latter is possible on distributed shared-memory (DSM) machines.\footnote{If a DSM machine has a cache-coherence mechanism, then we consider it to be a CC machine.} As explained later, it is generally more difficult to design local-spin algorithms for DSM machines than for CC machines.

In this paper, several results concerning the time complexity of local-spin mutual exclusion algorithms are presented. The notion of time complexity assumed is that given by the remote-memory-references (RMR) measure [2]. Under this measure, an algorithm’s time complexity is defined as the total number of remote memory references required in the worst case by one process to enter and then exit its critical section once. An algorithm may have different RMR time complexities on CC and DSM machines, because on CC machines, variable locality is dynamically determined, while on DSM machines, it is statically determined.

The main focus of this paper is mutual exclusion algorithms implemented using fetch-and-\(\phi\) primitives. A fetch-and-\(\phi\) primitive is characterized by a particular function \(\phi\) (which we assume to be deterministic), accesses a single variable atomically, and has the effect of the following pseudo-code, where \(\text{var}\) is the variable accessed.

\[
\text{fetch-and-}\phi(\text{var}, \text{input})
\]

\[
\text{old} := \text{var};
\]

\[
\text{var} := \phi(\text{old}, \text{input});
\]

\[
\text{return}(\text{old})
\]

In this paper, we distinguish between fetch-and-\(\phi\) primitives that are comparison primitives and those that are not. A comparison primitive conditionally updates a shared variable after first testing that its value meets some condition; examples include compare-and-swap and test-and-set.\footnote{compare-and-swap and test-and-set are ordinarily defined to return a boolean condition indicating if the comparison succeeded. In this paper, we instead assume that each returns the accessed variable’s original value, as in [5]. It is straightforward to modify any algorithm that uses the boolean versions of these primitives to instead use the versions considered in this paper.} Non-comparison primitives update variables unconditionally; examples include fetch-and-increment and fetch-and-store.

In recent work [1], we established a time-complexity lower bound of \(\Omega(\log N/\log\log N)\) remote memory references for any \(N\)-process mutual exclusion algorithm based on reads, writes, or comparison primitives. In contrast, several constant-time algorithms are known that are based on noncomparison fetch-and-\(\phi\) primitives.
3, 4, 9]. This suggests that noncomparison primitives may be the best choice to provide in hardware, if one is interested in implementing efficient blocking synchronization mechanisms.

Constant-time local-spin mutual algorithms that use noncomparison primitives have been proposed by T. Anderson [3], Graunke and Thakkar [4], and Mellor-Crummey and Scott [9]. In each of these algorithms, blocked processes wait within a “spin queue.” A process enqueues itself by using a fetch-and-\phi primitive to update a shared “tail” pointer; a process’s predecessor (if any) in the queue is indicated by the primitive’s return value. A process in the spin queue waits (if necessary) until released by its predecessor. Although these algorithms follow a common strategy, they vary in the primitives used and the progress properties ensured. Some important attributes of each algorithm are listed below.

- T. Anderson’s algorithm uses fetch-and-increment and requires an underlying cache-coherence mechanism for spins to be local. Thus, it has \( O(1) \) RMR time complexity only on CC machines.

- Graunke and Thakkar’s algorithm uses fetch-and-store. This algorithm also requires an underlying cache-coherence mechanism and thus has \( O(1) \) RMR time complexity only on CC machines.

- Mellor-Crummey and Scott actually presented two variants of their algorithm, one that uses fetch-and-store, and a second that uses both fetch-and-store and compare-and-swap. In both, spins are local on both CC and DSM machines. However, the fetch-and-store variant is not starvation-free, and hence actually has unbounded RMR time complexity. The variant that also uses compare-and-swap is starvation-free and has \( O(1) \) RMR time complexity on both CC and DSM machines.

The existence of these algorithms gives rise to a number of intriguing questions regarding mutual exclusion algorithms. Is it possible to devise an \( O(1) \) algorithm for DSM machines that uses a single fetch-and-\phi primitive? Can such an algorithm be devised using primitives other than fetch-and-increment and fetch-and-store? Is it possible to automatically transform a local-spin algorithm for CC machines so that it has the same RMR time complexity on DSM machines? Given that the \( \Omega(\log N/\log \log N) \) lower bound mentioned above applies to algorithms that use comparison primitives, we know that there exist fetch-and-\phi primitives that are not sufficient for constructing \( O(1) \) algorithms. For such primitives, what is the most efficient algorithm that can be devised? Can we devise a ranking of synchronization primitives that indicates the singular characteristic of a primitive that enables a certain RMR time complexity (for mutual exclusion) to be achieved? Such a ranking would provide information relevant to the implementation of blocking synchronization mechanisms that
is similar to that provided by Herlihy’s wait-free hierarchy [5], which is relevant to nonblocking mechanisms.3

The only prior work known to us that seeks to address (some of) these questions is a paper presented at ICDCS ’99 by Huang [6]. Huang presented an algorithm that uses only fetch-and-store and that has constant amortized RMR time complexity in DSM systems; that is, in any execution of the algorithm in such a system, the number of remote memory references divided by the number of critical-section entries is constant. The results of this paper, which are outlined below, extend those of Huang in two important ways. First, our results pertain to a wide class of primitives. Second, we do not rely on amortization in calculating time complexities.

**Contributions of this paper.** Our main contribution is a generic $N$-process fetch-and-$\phi$-based local-spin mutual exclusion algorithm that has $O(1)$ RMR time complexity on both CC and DSM machines. This algorithm is “generic” in the sense that it can be implemented using any fetch-and-$\phi$ primitive of rank $2N$. Informally, a primitive of rank $r$ has sufficient symmetry-breaking power to linearly order up to $r$ invocations of that primitive. Our generic algorithm breaks new ground because it shows that $O(1)$ RMR time complexity is possible using a wide range of primitives, on both CC and DSM machines. Thus, introducing additional primitives to ensure local spinning on DSM machines, as Mellor-Crummey and Scott did, is not necessary.

We present our generic algorithm by first giving a variant that is designed for CC machines. We then present a very general transformation that can be used to convert algorithms that locally spin on CC machines to ones that locally spin on DSM machines. This transformation is then applied to our algorithm. (This same transformation can also be applied to the algorithms of T. Anderson and Graumär and Thakkar.)

By applying our generic algorithm within an arbitration tree, one can easily construct a $\Theta(\log_r N)$ algorithm using any primitive of rank $r$, where $2 \leq r < N$. For the case $r = \Theta(N)$, this algorithm is clearly asymptotically time-optimal. However, we show that there exists a class of primitives with constant rank for which $\Theta(\log_r N)$ is not optimal. We show this by presenting a $\Theta(\log N / \log \log N)$ algorithm that can be implemented using any primitive that meets an additional condition, which is described next.

In designing a generic algorithm, the key issue to be faced is that of resetting a variable that is repeatedly updated by fetch-and-$\phi$ primitive invocations. In our generic algorithm, variables are reset using simple writes. In our $\Theta(\log N / \log \log N)$ algorithm, such a reset is performed using the fetch-and-$\phi$ primitive itself. That is,

3Herlihy’s hierarchy is concerned with computability: a primitive (or object) $X$ is stronger than a primitive (or object) $Y$ if $X$ can be used to implement $Y$ (in a non-blocking manner) but not vice versa. The ranking suggested here is not concerned with computability, but rather time complexity. Nonetheless, both rankings provide information concerning the usefulness of primitives. Herlihy’s hierarchy indicates which primitives should be supported in hardware if one is interested in implementing nonblocking algorithms; the proposed ranking indicates which primitives should be supported in hardware if one is interested in implementing scalable spin locks.
this algorithm requires that a *self-resettable* primitive (of rank at least three) be used. If a *fetch-and-ϕ* primitive is self-resettable, then the primitive itself can be used to reset a variable that has been updated using that primitive, i.e., it is not necessary to perform resets using write operations. Using a self-resettable primitive, a variable can be reset by an operation that returns the variable’s old value. In our $\Theta(\log N/\log \log N)$ algorithm, this fact is exploited, with a resulting asymptotic improvement in time complexity for primitives of rank $o(\log N)$. It follows from the $\Omega(\log N/\log \log N)$ lower bound mentioned above that this algorithm is time-optimal for certain self-resettable primitives of constant rank.

**Organization.** The rest of this paper is organized as follows. In Sec. 2, we present needed definitions. Then, in Sec. 3, we present our generic algorithm. The $\Theta(\log N/\log \log N)$ algorithm mentioned above is then presented in Sec. 4. We end the paper with concluding remarks in Sec. 5.

## 2 Definitions

Due to space constraints, we refrain from giving a definition of the mutual exclusion problem; such a definition can be found in any concurrent algorithms textbook (e.g., [8]). We hereafter let $N$ denote the number of processes in the system, and assume that each process has a unique process identifier in the range $0, \ldots, N - 1$.

We assume the existence of a *generic fetch-and-ϕ* primitive, as defined in Sec. 1. We will use “$\text{VarType}$” to denote the type of the accessed variable $\text{Var}$. (The accessed variable’s type is part of the definition of such a primitive.) For example, for a *fetch-and-increment* primitive, $\text{VarType}$ would be $\text{integer}$, and for a *test-and-set* primitive, it would be $\text{boolean}$. In our algorithms, we use $\bot$ to denote the initial value of a variable accessed by a *fetch-and-ϕ* primitive (e.g., if $\text{VarType}$ is $\text{boolean}$, then $\bot$ would denote either $\text{true}$ or $\text{false}$). We now define the notion of a “rank,” mentioned earlier.

**Definition:** The *rank* of a *fetch-and-ϕ* primitive is the largest integer $r$ satisfying the following.

For each process $p$, there exists a constant array $\alpha[p][0..k_p - 1]$ of input values (for some $k_p$), such that if $p$ performs a sequence of *fetch-and-ϕ* invocations as specified below on a variable $v$ (of type $\text{VarType}$) that is initially $\bot$ (for some choice of $\bot$),

$$\text{for } i := a_p \text{ to } \infty \text{ do } \text{fetch-and-ϕ}(v, \alpha[p][i \mod k_p]) \text{ od}$$

where $a_p$ is some integer value, then in any interleaving of these invocations by the $N$ different
processes, (i) any two invocations among the first \( r - 1 \) by different processes write different values to \( v \), (ii) any two successive invocations among the first \( r - 1 \) by the same process write different values to \( v \), and (iii) of the first \( r \) invocations, only the first invocation returns \( \perp \).

A fetch-and-\( \phi \) primitive has infinite rank if the condition above is satisfied for arbitrarily large values of \( r \). \( \Box \)

As our generic algorithm shows, a fetch-and-\( \phi \) primitive with rank \( r \) has enough power to linearly order \( r \) invocations by possibly different processes unambiguously. Note that it is not necessary for the primitive to fully order invocations by the same process, since each process can keep its own execution history.

**Examples.** An \( r \)-bounded fetch-and-increment primitive on a variable \( v \) with range \( 0, \ldots, r - 1 \) is defined by
\[
\phi(\text{old, input}) = \min(r - 1, \text{old} + 1).
\]
(In this primitive, the input parameter is not used, and hence we may simply assume \( \alpha[p][j] = \perp \) for all \( p \) and \( j \).) If \( v \) is initially 0, then any \( r \) consecutive invocations on \( v \) return distinct values, \( 0, 1, \ldots, r - 1 \). Moreover, any further invocation (after the \( r \)th) returns \( r - 1 \), which is the same as the return value of the \( r \)th invocation. Therefore, an \( r \)-bounded fetch-and-increment primitive has rank \( r \), and an unbounded fetch-and-increment primitive has infinite rank.

For fetch-and-increment primitives, the input parameter \( \alpha \) is extraneous. However, this is not the case for other primitives. As a second example, consider a fetch-and-store primitive on a variable that is large enough to hold \( 2N + 1 \) distinct values (\( 2N \) pairs \((p, 0)\) and \((p, 1)\), where \( p \) is a process, and an additional initial value \( \perp \)). It is easily shown that fetch-and-store has infinite rank. This follows by defining \( \alpha[p][j] = (p \cdot j \mod 2) \). (Informally, each process may write the information "this is an (even/odd)-indexed invocation by process \( p \)" each time.) It also follows that an unbounded fetch-and-store primitive has infinite rank.

## 3 A Constant-time Generic Algorithm

In this section, we present an \( O(1) \) mutual exclusion algorithm that uses a generic fetch-and-\( \phi \) primitive, which is assumed to have rank at least \( 2N \). Two variants of the algorithm are presented, one for CC machines and one for DSM machines. In local-spin algorithms for DSM machines, each process must have its own dedicated spin variables (which must be stored in its local memory module). In contrast, in algorithms for CC machines, processes may share spin variables, because each process can read a different cached copy. Because of this flexibility, algorithms for CC machines tend to be a bit simpler than those for DSM machines. This is why we present separate algorithms. Our CC algorithm, denoted G-CC, is presented first, and then its DSM counterpart,
### shared variables

- \( \text{CurrentQueue} \): 0, 1;
- \( \text{Tail} \): \( \text{array[0, 1]} \) of \( \text{Vtype} \) initially \( \perp \);
- \( \text{Position} \): \( \text{array[0, 1]} \) of \( 0..2N-1 \) initially 0;
- \( \text{Signal} \): \( \text{array[0, 1]}[\text{Vtype}] \) of \text{boolean} initially false;
- \( \text{Active} \): \( \text{array[0..N-1]} \) of \text{boolean} initially false;
- \( \text{QueueIdx} \): \( \text{array[0..N-1]} \) of \( (\perp, 0, 1) \);
- \( \text{Waiter1} \): \( \text{array[0..N-1]} \) of \( (\perp, 0, N-1) \);
- \( \text{Waiter2} \): \( \text{array[0, 1]}[\text{Vtype}] \) of \( (\perp, 0..N-1) \);
- \( \text{Spin} \): \( \text{array[0..N-1]} \) of \text{boolean} initially false

### private variables

- \( \text{idx} \): 0, 1;
- \( \text{counter} \): \text{integer};
- \( \text{prev, self, old} \): \text{Vtype};
- \( \text{pos} \): \( 0..2N-1 \);
- \( q \): \( 0..N-1 \);
- \( \text{next} \): \( (\perp, 0..N-1) \);
- \( \text{flag} \): \text{boolean}

---

Figure 1: Variables used in Algorithms G-CC and G-DSM.

![Figure 1](image-url)

The two algorithms and associated variable declarations are shown in Figs. 1–3. Each algorithm is specified by giving `Acquire` and `Release` procedures, which are invoked by a process to perform its entry and exit sections, respectively. In both algorithms, “\text{await} B,” where \( B \) is a boolean expression, is used as a shorthand for the busy-waiting loop “\text{while } \neg B \text{ do } */ \text{null} */ \text{od}.”

**Reset mechanism.** When trying to implement a mutual exclusion algorithm using a generic `fetch-and-\phi` primitive — of which only its rank \( r \) is known — the primary problem that arises is the following.

If the primitive is invoked more than \( r \) times to access a variable, then it may not be able to provide enough information for processes to order themselves. Therefore, the algorithm must provide a means of resetting such a variable before it is accessed \( r \) times.

Because we are using a primitive of rank \( 2N \), we need a mechanism for resetting a variable accessed by the primitive before it is accessed \( 2N \) times. We do this in Algorithm G-CC by using two “waiting queues,” indexed 0 and 1. Associated with each queue \( j \) is a “tail pointer,” \( \text{Tail}[j] \). In its entry section, a process enqueues itself onto one of these two queues by using the `fetch-and-\phi` primitive to update its tail pointer, and waits on its predecessor, if necessary. At any time, one of the queues is designated as the “current” queue, which is indicated by the shared variable \( \text{CurrentQueue} \). The other queue is called the “old” queue. The algorithm switches between the two queues over time in a way that ensures that each tail pointer is reset before being accessed \( 2N \) times. We now describe the reset mechanism in detail.

When a process invokes the `Acquire` routine, it determines which queue is the current queue by reading the variable \( \text{CurrentQueue} \) (line 3 of Fig. 2), and then enqueues itself onto that queue using the `fetch-and-\phi` primitive (lines 5–7). If \( p \) is not at the head of its queue \( (p.\text{prev} \neq \perp) \), then it waits until its predecessor in the queue updates the spin variable \( \text{Signal}[p.\text{idx}][p.\text{prev}] \) (line 9), which \( p \) then resets (line 10).

Figure 3: Algorithm G-DSM: Generic algorithm for DSM machines. Lines different from Fig. 2 are shown with boldface line numbers.
Figure 4: The structure of Algorithm G-CC. (a) The overall structure. This figure shows a possible state of execution when the current queue is queue 0. (The “finished” processes may be duplicated, because a process may execute its critical section multiple times.) (b) A state before CurrentQueue is updated. (c) A state just after CurrentQueue is updated. (d) A process (in its exit section) in the current queue waiting for another in the old queue.

Note that it is possible for a process $q$ to read CurrentQueue before another process updates CurrentQueue to switch to the other queue. Such a process $q$ will then enqueue itself onto the old queue. Thus, both queues may possibly hold waiting processes. To arbitrate between processes in the two queues, an extra two-process mutual exclusion algorithm is used. A process competes in this two-process algorithm after reaching the head of its waiting queue using the routines Acquire$_2$ and Release$_2$, with the index of its queue as a “process identifier” (lines 11 and 14). This is illustrated in Fig. 4(a), where the current queue is queue 0. Note that this extra two-process algorithm can be implemented from reads and writes in $O(1)$ time [10].
As explained above, some process must reset the current queue before it is accessed 2N times. To facilitate this, each queue \( j \) has an associated shared variable \( \text{Position}[j] \). This variable indicates the relative position of the current head of the queue, starting from 0. For example, in Fig. 4(a), the head of queue 0 is at position 2, and hence \( \text{Position}[0] = 2 \). A process in queue \( j \) updates \( \text{Position}[j] \) while still effectively in its critical section (lines 12 and 13). Thus, \( \text{Position}[j] \) cannot be concurrently updated by different processes.

A process exchanges the role of the two queues after completing its critical section if it is at position \( N \) in the current queue (lines 20–22). Insets (b) and (c) of Fig. 4 show the state of the two queues before and after such an exchange. In order to exchange the queues, we must ensure the following invariant.

**Invariant** If a process executes its critical section after having acquired position \( N \) of the current queue, then no process is in the old queue. 

\[(I1)\]

(A process is considered to be “in” the old queue if it read the index of that queue from \( \text{CurrentQueue} \). In particular, that process may be yet to update the queue’s tail pointer.) Given this invariant, a process at position \( N \) may safely reset the old queue and exchange the queues. Invariant \((I1)\) is a direct consequence of the following invariant. (Recall that process identifiers range from 0 to \( N - 1 \).)

**Invariant** If a process executes its critical section after having acquired position \( pos \) of the current queue, and if \( pos > q \), then process \( q \) is not in the old queue.

\[(I2)\]

To maintain \((I2)\), each process \( p \) has two associated variables, \( \text{Active}[p] \) and \( \text{QueueId}[p] \), which indicate (respectively) whether process \( p \) is active, and if so, which queue it is executing in (lines 1, 2, 4, and 24). If a process \( p \) executes at position \( q \) (\( < N \)) in the current queue, then in its exit section, \( p \) checks \( \text{QueueId}[q] \) in order to see if process \( q \) is in the old queue (line 15); if that is the case, then \( p \) waits until \( q \) finishes its critical section (lines 17 and 18) before signaling a possible successor (i.e., a process at position \( q + 1 \) in the current queue) that it is now at the head of that queue (line 23). This situation is depicted in Fig. 4(d).

Although \( p \) waits for \( q \), starvation freedom is guaranteed, because \( q \) is in the old queue, and hence makes progress independent of the current queue. Only the current queue is stalled until \( q \) finishes execution. (The fact that \( p \) may have to wait for a significant duration in its exit section may be a cause for concern. However, with a slightly more complicated handshake, such waiting can be eliminated. The idea is to require process \( p \) to instruct process \( q \) to signal \( p \)'s successor after \( q \) finishes its critical section. Therefore, \( p \) may finish execution without waiting for \( q \). For simplicity, this handshake has not been added to Algorithm G-CC.)
We still must show that using a \textit{fetch-and-\phi} primitive of rank $2N$ is sufficient. Suppose that process $p$ acquires position $N$ of queue 0 when it is the current queue. We claim that at most $N - 1$ processes may be enqueued onto queue 0 after $p$ and before the queues are exchanged again. For a process $q$ to enqueue itself onto queue 0 after $p$, it must have read the value of $\text{CurrentQueue}$ before it was updated by $p$. For $q$ to enqueue itself a second time onto queue 0, it must read $\text{CurrentQueue} = 0$ again, after $\text{CurrentQueue} = 1$ was established by $p$. This implies that the two queues have been exchanged again. (We remind the reader that, by the explanation above, the queues will not be exchanged again until there are no processes in queue 0.) Thus, after $p$ establishes that queue 1 is current, and while queue 0 continues to be the old queue, at most $N - 1$ processes may be enqueued (after $p$) onto queue 0. Thus, a rank of $2N$ is sufficient.

\textbf{Time complexity.} The busy-waiting loops at lines 9, 17, and 18 in Fig. 2 are read-only loops in which variables are read that may be updated by a unique process. On a CC machine, the first read of such a variable generates a cached copy, and hence subsequent reads until the variable is updated are handled in-cache. In all cases, such a variable can be updated a constant number of times before the waiting condition is established. Thus, each busy-waiting loop generates a constant number of remote memory references. (This analysis ignores any invalidations or displacements of cached variables due to cache associativity or capacity constraints.) Because there are no loops in the algorithm aside from busy-waiting loops, it follows that the RMR time complexity of Algorithm G-CC is $O(1)$ on CC machines. Thus, we have the following lemma.

\textbf{Lemma 1} If the underlying fetch-and-\phi primitive has rank at least $2N$, then Algorithm G-CC is a correct, starvation-free mutual exclusion algorithm with $O(1)$ RMR time complexity in CC machines. \hfill $\Box$

\textbf{Algorithm G-DSM.} We now explain how to convert Algorithm G-CC into Algorithm G-DSM. The key idea of this conversion is a simple transformation of each busy-waiting loop, which we examine here in isolation. This transformation generalizes one presented earlier by us \cite{7}. In Algorithm G-CC, all busy waiting is by means of statements of the form \textbf{“await B,”} where $B$ is some boolean condition. Moreover, if a process $p$ is waiting for condition $B$ to hold, then there is a unique process that can establish $B$, and once $B$ is established, it remains true, until $p$’s \textbf{“await B”} statement terminates.

In Algorithm G-DSM, each statement of the form \textbf{“await B”} has been replaced by the code fragment on the left below (see lines 13–20 and 28–36 in Fig. 3), and each statement of the form \textbf{“$B := true$”} by the code fragment on the right (see lines 4–8, 41–45, and 46–50).
a: Acquire₂(\mathcal{J}, 0);
b: flag := B;
c: Waiter[\mathcal{J}] := \text{if } flag \text{ then } \bot \text{ else } p;
d: Spin[p] := \text{false};
e: Release₂(\mathcal{J}, 0);
f: if \neg flag then
  g: \quad \text{await } Spin[p];
h: \quad \text{Waiter}[\mathcal{J}] := \bot
i: \quad \text{Acquire₂(\mathcal{J}, 1)};
j: \quad B := \text{true};
k: \quad \text{next} := \text{Waiter}[\mathcal{J}];
l: \quad \text{Release₂(\mathcal{J}, 1)};
m: \quad \text{if } \text{next} \neq \bot \text{ then } \text{Spin[next]} := \text{true}
i

The variable \(\text{Waiter}[\mathcal{J}]\) is assumed to be initially \(\bot\), and \(\text{Spin}[p]\) is a spin variable used exclusively by process \(p\) (and, hence, it can be stored in memory local to \(p\)). \text{Acquire₂} and \text{Release₂} represent an instance of a two-process mutual exclusion algorithm, indexed by \(\mathcal{J}\). To see that this transformation is correct, assume that a process \(p\) executes lines a–h while another process \(q\) executes lines i–m. Since lines b–d and j–k execute within a critical section, lines b–d precede lines j–k, or \textit{vice versa}. If \(b\)–\(d\) precede \(j\)–\(k\), and if \(B = \text{false}\) holds before the execution of \(b\)–\(d\), then \(p\) assigns \(\text{Waiter}[\mathcal{J}] := p\) at line c, and initializes its spin variable at line d. Process \(q\) subsequently reads \(\text{Waiter}[\mathcal{J}] = p\) at line k, and establishes \(\text{Spin}[p] = \text{true}\) at line m, which ensures that \(p\) is not blocked. On the other hand, if lines j–k precede lines b–d, then process \(q\) reads \(\text{Waiter}[\mathcal{J}] = \bot\) (the initial value) at line k, and does not update any spin variable at line m. Since process \(p\) executes line b after \(q\) executes line j, \(p\) preserves \(\text{Waiter}[\mathcal{J}] = \bot\), and does not execute lines g and h. Given the correctness of this transformation, we have the following.

**Lemma 2** If the underlying fetch-and-\(\phi\) primitive has rank at least \(2N\), then Algorithm G-DSM is a correct, starvation-free mutual exclusion algorithm with \(O(1)\) RMR time complexity in DSM machines.

The transformation above also can be applied to the algorithms of T. Anderson [3] and Graumäe and Thakkar [4]. In each case, the two-process mutual algorithm actually can be avoided by utilizing the specific fetch-and-\(\phi\) primitive used (fetch-and-increment and fetch-and-store, respectively).

If we have a fetch-and-\(\phi\) primitive with rank \(r\) \((4 \leq r < 2N)\), then we can arrange instances of Algorithm G-DSM in an arbitration tree, where each process is statically assigned a leaf node and each non-leaf node consists of an \([r/2]\)-process mutual exclusion algorithm, implemented using Algorithm G-DSM. Because this arbitration tree is of \(\Theta(\log_r \, N)\) height, we have the following theorem. (Note that for \(r = 2\) or \(3\), a \(\Theta(\log_r \, N)\) algorithm is possible without even using the fetch-and-\(\phi\) primitive [10].)

**Theorem 1** Using any fetch-and-\(\phi\) primitive of rank \(r \geq 2\), starvation-free mutual exclusion can be implemented with \(\Theta(\log_{\min(r, N)} N)\) RMR time complexity on either CC or DSM machines.
4 \( \Theta(\log / \log \log N) \) Algorithm

The time-complexity bound in Theorem 1 is clearly tight for \( r = \Theta(N) \). In this section, we show that for some primitives of rank \( r = o(\log N) \), it is not tight, provided that \( r \) is at least three. This follows from Algorithm T, shown in Fig. 10, which has \( \Theta(\log / \log \log N) \) RMR time complexity on both DSM and CC machines. In this algorithm, it is assumed that the fetch-and-\( \phi \) primitive used has a rank of at least three, and is “self-resettable,” as defined below.

**Definition:** A fetch-and-\( \phi \) primitive with rank \( r \) is *self-resettable* if the following hold:

- Let \( \alpha[p][0..k_p-1] \) be defined as in the definition of rank, and let each process execute the `for` loop shown in that definition. Then, in any interleaving of an arbitrary number of these fetch-and-\( \phi \) primitive invocations by the \( N \) different processes, only the first invocation returns \( \bot \).

- For each \( \alpha[p][i] \), there is an associated value \( \beta[p][i] \) such that \( \phi(\bot, \alpha[p][i]), \beta[p][i]) = \bot \). That is, if the invocation of the fetch-and-\( \phi \) primitive on \( v \) by process \( p \) returns \( \bot \), and if no other process accesses \( v \), then \( p \) may reset the variable by invoking the primitive again with a “reset” parameter.

Recall that in the generic algorithms of the previous section, devising a way of resetting the Tail variables was the key problem to be addressed. Because we could assume so little of the semantics of the fetch-and-\( \phi \) primitive being used, simple write operations were used to reset these variables. If a self-resettable fetch-and-\( \phi \) primitive is available, then that primitive itself can be used to perform such a reset.

In order to hide certain low-level details in Algorithm T we will assume the availability of two operations, fetch-and-update and fetch-and-reset. A fetch-and-update operation on a variable \( v \) invokes the fetch-and-\( \phi \) primitive being used with the parameter \( \alpha[p][i_v] \) (where \( i_v \) is a private counter variable associated with \( v \)), increments \( i_v \), and returns the old value of \( v \) (i.e., the return value of the fetch-and-\( \phi \) primitive) and the new value of \( v \) (which can be determined by \( \phi(v, \alpha[p][i_v]) \)). A fetch-and-reset operation on a variable \( v \) invokes the fetch-and-\( \phi \) primitive with the parameter \( \beta[p][i_v] \), and also returns the old and new values of \( v \).

As a stepping stone toward Algorithm T, we present a simpler algorithm, Algorithm T0, with a similar structure. Algorithm T0, which is shown in Fig. 6, uses an arbitration tree, each node \( n \) of which is represented by a “local variable” Lock[\( n \)] of type Node-Type. Such a variable can hold up to two process identifiers and is accessible by two atomic operations, AcquireNode and ReleaseNode, as shown in Fig. 5, in addition to ordinary read and write operations. Informally, a value of \((\bot, \bot)\) represents an available node; \((p, \bot)\), where \( p \neq \bot \),
type Node_Type = record winner, waiter: (0..N - 1, ⊥) end;
/* if winner = ⊥, then waiter = ⊥ also holds. */

process p :: /* 0 ≤ p < N */
function Acquire_Node (t: Node_Type):
  (WINNER, PRIMARY_WAITER, SECONDARY_WAITER)
/* atomically do the following */
if t = (⊥, ⊥) then
  t := (p, ⊥); return WINNER
elsif t.winner = ⊥ then
  t.winner := p; return PRIMARY_WAITER
else
  return SECONDARY_WAITER
fi

function Release_Node (t: Node_Type): (SUCCESS, FAIL)
/* atomically do the following */
if t.winner ≠ p then
  /* error: should not happen */
elsif t = (p, ⊥) then
  t := (⊥, ⊥); return SUCCESS
else
  return FAIL
fi

Figure 5: Definitions of Node_Type, Acquire_Node, and Release_Node. Note that Acquire_Node and Release_Node are assumed to execute atomically.

represents a situation in which process p has acquired the node and no other process has since accessed that node; (p, q), where p ≠ ⊥ and q ≠ ⊥, represents a situation in which p has acquired the node and another process q is waiting at that node (perhaps along with some other processes).

Arbitration tree and waiting queue. The structure of the arbitration tree is illustrated in Fig. 7. The tree is of degree m = \sqrt{log N}. Each process is statically assigned to a leaf node, which is at level MAX_LEVEL. (The root is at level 1.) Since the tree has N leaf nodes, MAX_LEVEL = Θ(log_m N) = Θ(log N/log log N).

To enter its critical section, a process p traverses the path from its leaf up to the root and attempts to acquire each node on this path. If p acquires the root node, then it may enter its critical section. As explained shortly, p may also be “promoted” to its critical section while still executing within the tree. (In that case, p may have acquired only some of the nodes on its path.) In either case, upon exiting its critical section, p traverses its path in reverse, releasing each node it has acquired.

In addition to the arbitration tree, a serial waiting queue, WaitingQueue, is used. This queue is accessed by a process only within its exit section. A “barrier” mechanism is used that ensures that multiple processes do not execute their exit sections concurrently. As a result, the waiting queue can be implemented as a sequential data structure. It is accessible by the usual Enqueue and Dequeue operations, and also an operation Remove(WaitingQueue, p), which removes process p from inside the queue, if present; it is straightforward to implement each of these operations in O(1) time. When a process p, inside its exit section, discovers another waiting process q, p adds q to the waiting queue. In addition, p dequeues a process r from the queue (if the queue is nonempty), and “promotes” r to its critical section. (This mechanism is rather similar to helping mechanisms used in wait-free algorithms [5:].

Figure 6: Algorithm T0: A tree-structured algorithm using a Node Type object.

Arbitration at a node. As mentioned above, associated with each (non-leaf) node n is a “lock variable” Lock[n], which represents the state of that node. The structure of such a node is illustrated in Fig. 8. In its entry section, a process p may try to acquire node n only if it has already acquired some child of n. In order to acquire node n, p executes Acquire_Node(Lock[n]). Assume that the old value of Lock[n] is (q,r). There are three possibilities to consider.

- If q = ⊥ holds, then p has established Lock[n] = (p, ⊥) and has acquired node n. In this case, p becomes the winner of node n, and proceeds to the next level of the tree.
- If q ≠ ⊥ and r = ⊥ hold, then p has established Lock[n] = (q, p), in which case it becomes the primary
Each node has degree $m = \sqrt{\log N}$.

**Figure 7:** Arbitration tree of Algorithm T0 and Algorithm T.

A **waiter** at node $n$. In this case, $p$ stops at node $n$ and waits until it is “promoted” to its critical section by some other process.

- Otherwise, the value of $\text{Lock}[n]$ is not changed, in which case $p$ is a secondary waiter at node $n$. In this case, $p$ also waits at node $n$ until it is promoted.

Next, consider the behavior of a process $p$ in its exit section. There are two possibilities to consider, depending on $p$’s execution history in its entry section.

- If $p$ acquired node $n$ in its entry section, then $p$ has established $\text{Lock}[n] = (p, \bot)$. In this case, $p$ tries to release node $n$ by executing $\text{ReleaseNode}(\text{Lock}[n])$. If no other process has updated $\text{Lock}[n]$ between $p$’s executions of $\text{AcquireNode}(\text{Lock}[n])$ and $\text{ReleaseNode}(\text{Lock}[n])$, then node $n$ is successfully released (i.e., $\text{Lock}[n]$ transits to $(\bot, \bot)$). In this case, $p$ descends the tree and continues to release other nodes it has acquired.

On the other hand, if some other process has updated $\text{Lock}[n]$ between $p$’s two invocations, then let $q$ be the first such process. As explained above, $q$ must have changed $\text{Lock}[n]$ from $(p, \bot)$ to $(p, q)$, thus
designating itself as the primary waiter at node \( n \). In this case, \( p \) adds \( q \) to the waiting queue. (Note that \( p \) does not enqueue any secondary waiters, i.e., processes that accessed \( \text{Lock}[n] \) after \( q \).) Process \( p \) then releases node \( n \) by writing (not via calling \( \text{ReleaseNode} \)) \( \text{Lock}[n] := (\bot, \bot) \), and descends the tree.

- If \( p \) was promoted at node \( n \), then \( p \) has not acquired node \( n \), and hence is not responsible for releasing node \( n \). Instead, \( p \) examines every child of node \( n \) (specifically, \( \text{Lock[child]} \), where \( \text{child} \) is a child of \( n \)) to determine if any “secondary waiters” at node \( n \) exist. \( p \) adds such processes to the waiting queue.

The algorithm uses an additional mechanism that ensures the following invariant, as explained shortly.

**Invariant** If a process \( p \) acquires node \( n \), and if another process \( q \) later becomes the primary waiter of node \( n \), then \( q \) examines every child of node \( n \) after node \( n \) is released by \( p \) or by some other process on behalf of \( p \) (see below).

Assuming this invariant, we can easily show that each process eventually either acquires the root, or is added to the waiting queue by some other process. In particular, at node \( n \), the winner always proceeds to the next level, and the primary waiter \( q \) is eventually enqueued by the winner or by some other process (the latter could happen if waiting processes on \( q \)'s path lower in the tree are promoted). Thus, we only have to show that a secondary waiter is eventually enqueued. In order for a process \( r \) to become a secondary waiter at node \( n \), it must first acquire a child node \( n' \) of \( n \), and then execute \( \text{AcquireNode(Lock[n])} \) while \( \text{Lock} = (p, q) \) holds, for some winner \( p \) and primary waiter \( q \). Invariant (I3) guarantees that \( q \) has yet to examine the child nodes of \( n \). Therefore, \( q \) eventually examines node \( n' \), and adds \( r \) to the waiting queue (if it has not already been added by some other process).

Finally, since the waiting queue is checked every time a process executes its exit section, it follows that the algorithm is starvation-free.

As explained above, processes exiting the arbitration tree form two groups: the promoted processes and the non-promoted processes (i.e., those that successfully acquire the root). To arbitrate between these two groups, an additional two-process mutual exclusion algorithm is used. The manner in which this algorithm and the barrier mentioned previously are used is illustrated in Fig. 9.

**Further details.** Having explained the basic structure of the algorithm, we now present a more detailed overview. We begin by considering the shared variables used in the algorithm, which are listed in Fig. 6. \( \text{Lock} \) and \( \text{WaitingQueue} \) have already been explained. \( \text{Spin}[p] \) is a dedicated spin variable for process \( p \). \( \text{Promoted} \) is
Figure 9: The exit sections of Algorithm T0 and Algorithm T. Dashed and dotted lines represent information/signal flow.

used to hold the identity of any promoted process. This variable is used to ensure that multiple processes are not promoted concurrently, which is required in order to ensure that the additional two-process mutual exclusion algorithm is accessed by only one promoted process at a time. \( \text{InTree}[p] \) indicates whether \( p \) is accessing the arbitration tree in its entry section, and may be checked by another process (in its exit section) in order to maintain (13).

We now consider the Acquire and Release procedures in Fig. 6 in some detail. A process \( p \) in its entry section first initializes its spin variable (line 1), begins accessing the arbitration tree (line 2), and automatically acquires its leaf node (line 3). It then ascends the arbitration tree (lines 4–10). Function \( \text{Node}(p, \text{lev}) \) is used to return the index of the node at level \( \text{lev} \) in \( p \)'s path (line 5). Process \( p \) tries to acquire each node it visits by executing line 6. If it succeeds, then it ascends to the next level; otherwise, it finishes accessing the arbitration tree (line 7), and spins at line 8 until it is promoted by some other process. If \( p \) acquires the root node, then it executes the two-process entry section using “0” as a process identifier (line 13). Otherwise, it executes the two-process entry section using “1” as a process identifier (line 10). The private variable break_level stores the level at which \( p \) exited the for loop (lines 9 and 12).

In its exit section, \( p \) waits until the barrier is opened (line 14) and then executes the two-process exit section (lines 16 and 17). The barrier is specified by two procedures Wait and Signal, which ensure that \( p \) waits at line 14 if another process is executing within lines 15–40. Because Wait is invoked within a critical section, it is straightforward to implement these procedures in \( O(1) \) time. In CC machines, \( \text{Wait} \) can be defined as “\text{await}...
Flag; Flag := false” and Signal as “Flag := true,” where Flag is a shared boolean variable. In DSM machines, a slightly more complicated implementation is required, which we omit due to space limitations.

If p was promoted at node n (i.e., break level > 0), then it examines Lock[n] (line 19). If p finds Lock[n].waiter = p at line 19, then p is the primary waiter at n, and was promoted before the winner of node n (given by Lock[n].winner) entered its critical section. This can happen because p may actually have been promoted by a primary waiter at a lower level. In this case, p waits until the winner finishes accessing the arbitration tree (line 21). (Note that this will not be a local-spin loop in a DSM machine. We will return to this issue shortly.) It then resets node n in place of the winner, and adds the winner to the waiting queue (lines 22 and 23). After that, p adds any process that has acquired a child node of n to the waiting queue (lines 24–27). Note that lines 19–23 ensure that Lock[n] is released at least once before lines 24–27 are executed, thus ensuring that (I3) holds.

Regardless of whether p was promoted, it tries to reopen each node that it acquired in its entry section (lines 28–33). For each such node n, p checks if it is still the winner (line 30); this may not be the case, if the primary waiter at node n executed lines 20–23 before p entered its critical section. If p is indeed the winner at node n, then it tries to reopen node n (line 31). p may fail to reopen node n only if node n has a primary waiter, in which case p enqueues the waiter and reopens the node using an ordinary write (lines 32 and 33). Finally, p resets its leaf node (line 34), makes sure that it is not contained in the waiting queue (line 35), and checks if there is any unfinished promoted process (lines 36 and 37). If not, then p dequeues and promotes a process from the waiting queue (if one exists) (lines 38–40). As a last step, p opens the barrier (line 41).

In order to compute the time complexity of the algorithm, note that \( \text{MAXLEVEL} = \Theta(\log N / \log \log N) \) holds. Therefore, the for loop in lines 4–10 iterates \( O(\log N / \log \log N) \) times and that in lines 28–33 iterates \( \Theta(\log N / \log \log N) \) times. Since the arbitration tree has degree \( \Theta(\sqrt{\log N}) \), the for loop in lines 24–27 iterates \( \Theta(\sqrt{\log N}) \) times, which is asymptotically dominated by \( \Theta(\log N / \log \log N) \). It follows that the worst-case time complexity of the algorithm is \( \Theta(\log N / \log \log N) \) provided all busy-waiting is by local spinning. The busy-waiting loop in line 8 spins on a local spin variable. The loop in line 21 does not, but it can be easily transformed so that all spinning is local (on DSM machines) using the technique in Sec. 3. Thus, Algorithm T0 (with the transformation of line 21) has \( \Theta(\log N / \log \log N) \) RMR time complexity on both DSM and CC machines.

**Algorithm T.** We now explain the differences between Algorithm T0 and Algorithm T, which is shown in Fig. 10. In Algorithm T, each lock variable is accessed by the fetch-and-update and fetch-and-reset operations.
defined earlier, instead of the *AcquireNode* and *ReleaseNode* operations in Fig. 5. Each such variable is assumed to have a type (*Vartype*) that is consistent with the given *fetch-and-ϕ* primitive being used, and is initially ⊥. The main problem associated with the use of a generic *fetch-and-ϕ* primitive is that we cannot use the same variable as both a lock variable and as a variable for storing process identifiers. In particular, even if a process *p* performs a successful *fetch-and-update*(*)v*) operation, the value written to *v* may be completely arbitrary; another process *q* may not be able to discover the winning process (that is, *p*) by reading *v*. Therefore, we need a pair of variables, one for each purpose.

Another problem is that, in its exit section, a winner *p* (at node *n*) may fail to discover the primary waiter. To see why this is so, consider the following scenario: *Lock*[*n*] is initially ⊥; *p* acquires node *n*, and writes *v₁* to *Lock*[*n*]; another process *q* accesses *Lock*[*n*], writes *v₂*, and becomes the primary waiter; yet another process *r* accesses *Lock*[*n*], and writes *v₁*. (This is allowed because the primitive may have rank three.) Thus, process *p* cannot detect *q* and *r* by reading *Lock*[*n*].

In order to solve this problem, note that such a situation may arise only if there are multiple waiters (*q* and *r* in this case). Therefore, we can design the entry section of each node as follows.

- First, a process executes *fetch-and-update*(*)Lock*[*n*][0]*) in order to become the primary winner at node *n*.
- If it fails, then it executes *fetch-and-update*(*)WaiterLock*[*n]*) in order to become the primary waiter.
- If it still fails, then it executes *fetch-and-update*(*)Lock*[*n*][1]*) in order to become the secondary winner at node *n*.
- If it fails all three, then it becomes a secondary waiter.

A process ascends the tree if it becomes either the primary winner or the secondary winner. Thus, now two processes can ascend the tree at each node. Note that a process may become the secondary winner only if it fails to become the primary waiter, i.e., only if there already exists a primary waiter. Also note that, if the primary winner fails to detect the primary waiter, then some process must become a secondary winner that knows that there exists a primary waiter.

We now explain the structure of Algorithm T in detail.

Each node *n* is represented by the following variables: *Lock*[*n*][0, 1], *Winner*[*n*][0, 1], *WaiterLock*[*n*], and *Waiter*[*n*]. Initially, all variables are ⊥, representing an available node. Variables *Lock*[*n*][0, 1] and *WaiterLock*[*n*] are used as lock variables, and are accessed by *fetch-and-update* and *fetch-and-reset* operations. If a process *p*

Figure 10: Algorithm T: A tree-structured algorithm using a generic self-resettable fetch-and-phi primitive of rank at least three. Variables not defined here are the same as in Fig 6.
invokes \textit{fetch-and-update} on a lock variable while it has a value of \bot, then \( p \) “acquires” that variable. A process that acquires \( \text{Lock}[n][0] \) (respectively, \( \text{WaiterLock}[n] \), \( \text{Lock}[n][1] \)) becomes the primary winner (respectively, primary waiter, secondary winner), and writes its identity to \( \text{Winner}[n][0] \) (respectively, \( \text{Waiter}[n] \), \( \text{Winner}[n][1] \)).

At each node \( n \) (at level \( lev \)), process \( p \) tries to acquire some variable of that node by invoking \textit{AcquireNode} (line 5, 14–25 in Fig. 10). If \( p \) becomes either the primary winner or the secondary winner, then it proceeds to the next level of the tree, as mentioned above. Otherwise, \( p \) stops at node \( n \) and waits until it is promoted, as in Algorithm T0. If \( p \) becomes the primary winner, then it also stores the new value of \( \text{Lock}[n][0] \) into a private variable \( \text{lock}[lev] \) (where \( lev \) is the level of node \( n \)), to be used in its exit section.

The following counterpart of (13) holds in Algorithm T.

\textbf{Invariant} If a process \( p \) acquires \( \text{Lock}[n][0] \) at node \( n \), and if another process \( q \) later becomes the primary waiter at node \( n \), then \( q \) examines every child of node \( n \) \textit{after} \( \text{Lock}[n][0] \) is released by \( p \) or by some other process on behalf of \( p \).

\textbf{(14)}

We now consider the behavior of a process \( p \) in its exit section, at a given node \( n \). The behavior is slightly more complicated than that in Algorithm T0. (For brevity, we do not restate properties that are common to both Algorithm T0 and T.)

\textbf{Case 1: \( p \) is the primary winner (lines 47–52).} Process \( p \) tries to release \( \text{Lock}[n][0] \) by invoking \textit{fetch-and-reset} (line 48). If the old value of \( \text{Lock}[n][0] \) (returned by \textit{fetch-and-reset}) is different from \( \text{lock}[lev] \), then there has been at least one other process, say \( q_1 \), that invoked \textit{fetch-and-update} on \( \text{Lock}[n][0] \) and failed to acquire that variable. Therefore, \( q_1 \) must have tried (or is about to try) to acquire \( \text{WaiterLock}[n] \).

If \( q_1 \) succeeds in acquiring \( \text{WaiterLock}[n] \), then it becomes the primary waiter; otherwise, there must be another primary waiter \( q_2 \). It follows that eventually there exists a primary waiter \( q \) (either \( q_1 \) or \( q_2 \)).

Therefore, \( p \) waits until \( \text{Waiter}[n] \neq \bot \) is established (line 49), at which point \( \text{Waiter}[n] = q \) must hold. It then adds \( q \) to the waiting queue (line 50). Process \( p \) then checks if the \textit{fetch-and-reset} operation has established \( \text{Lock}[n] = \bot \) (line 51), and if not, establishes this condition by a simple write (line 52). (Note that the \textit{fetch-and-reset} operation is guaranteed to write \( \bot \) only if \( \text{Lock}[n][0] \) has the same value as written by \( p \)'s last \textit{fetch-and-update} operation, which is not the case here.)

On the other hand, if the old value of \( \text{Lock}[n][0] \) equals \( \text{lock}[lev] \), then there are two possibilities: either \textbf{(i)} no other process accessed \( \text{Lock}[n][0] \) after \( p \) acquired it, or \textbf{(ii)} at least \textit{two} processes have done so. In either
case, the fetch-and-reset operation has successfully released Lock[n][0]. As explained before, in Case (ii),
the primary waiter of node n will be eventually detected by the secondary winner (if no other process elsewhere in
the tree detects it). Thus, p can safely descend the tree without taking further action.

Case 2: p is a primary/secondary waiter (lines 31–43). First, p checks if the primary winner still exists
(line 31), and if so, releases Lock[n][0] (lines 32–35) and adds the primary winner to the waiting queue (line 36).
This is done in order to maintain (I4), in the same way lines 20–23 of Algorithm T0 maintain (I3).

After that, p releases WaiterLock[n] if it is a primary waiter (line 37–39), and then examines every child of
node n (specifically, Lock[child][0,1], where child is a child of n) to determine if any secondary waiters at node
n exist (lines 40–43). p adds such processes to WaitingQueue.

Case 3: p is the secondary winner (lines 54–58). If p is the secondary winner, then it releases Lock[n][0]
by a simple write (lines 54 and 55). Then, p checks if there exists a primary waiter by examining WaiterLock[n]
(line 56), and if so, adds the primary waiter to WaitingQueue (lines 57 and 58).

In order to show that the algorithm is starvation-free, we only have to show that each primary or secondary
waiter is eventually enqueued onto the global waiting queue.

First, consider a secondary waiter r. In order for r to become a secondary waiter, at the time when r invokes
fetch-and-update( WaiterLock[n] ) (line 19), there must be a primary waiter q of n. As shown below, q eventually
executes its exit section, where it examines every child of n and adds r to the waiting queue.

Second, consider a primary waiter q at a node n. In order for q to become the primary waiter, at the time
when q invokes fetch-and-update( Lock[n][0] ) (line 15), there must be a primary winner p of n. We consider three
cases.

• First, if p detects q in its exit section, then p clearly adds q to the waiting queue.

• Second, if p detects another primary waiter r, which enters and then exits its critical section before q
  acquires WaiterLock[n], then r examines every child of n in its exit section. Since q must be a primary or
  secondary winner of some child of n, r discovers q and adds it to the waiting queue.

• Third, Assume that p does not detect the existence of the primary waiter in its exit section. That is, p
  finds prev = lock[lev] at line 48, and skips lines 49–52. In this case, there exists another process r that fails
  to acquire Lock[n][0]. If r becomes a primary waiter and then exits before q acquires WaiterLock[n], then r

22
detects $q$ as in the second case. Thus, assume that $r$ fails to acquire $WaiterLock[n]$. If $r$ fails because some other process $s$ has acquired $WaiterLock[n]$, then $s$ has exited before $q$ acquired $WaiterLock[n]$, and the reasoning is again similar to the second case. On the other hand, if $r$ fails because $q$ acquires $WaiterLock[n]$ before $r$, then either $r$ eventually becomes the secondary winner, or $r$ fails yet again because there exists another process $s$ that is the secondary winner. In either case, there eventually exists a secondary winner $(r$ or $s)$ that detects $q$ in its exit section.

Finally, note that every busy-waiting loop in Algorithm T is either a local-spin loop (line 8) or is executed inside a mutually exclusive region (lines 32, 33, 49, and 57). We can apply the technique in Sec. 3 and transform each of these non-local-spin loops into a local-spin loop (on DSM machines). Thus, we have the following theorem.

**Theorem 2** Using any self-resettable fetch-and-phi primitive of rank $r \geq 3$, starvation-free mutual exclusion can be implemented with $\Theta(\log N/\log \log N)$ time complexity on either CC or DSM machines. 

It can be shown that our previous $\Omega(\log N/\log \log N)$ lower-bound proof [1] applies to certain systems that use fetch-and-phi primitives of constant rank. The proof inductively extends computations so that information flow among processes is limited. If, at some induction step, a variable $v$ is accessed by many processes, then information flow is kept low by ensuring that $v$ may be assigned $O(1)$ different values during this induction step. Therefore, our lower bound applies to any fetch-and-phi primitive satisfying the following: any consecutive invocations of the primitive by different processes can be ordered so that only $O(1)$ different values are returned. It follows that, for self-resettable fetch-and-phi primitives with a constant rank of at least three that satisfy this condition, Algorithm T is asymptotically time-optimal. Examples of such primitives include a fetch-and-increment/decrement primitive with bounded range 0..2, a variant of compare-and-swap that allows two different compare values to be specified, and the simultaneous execution of a test-and-set and a write operation on different bits of a variable.

## 5 Concluding Remarks

We have shown that any fetch-and-phi primitive of rank $r$ can be used to implement a $\Theta(\log_{\min}(r,N) \cdot N)$ mutual exclusion algorithm, on either DSM or CC machines. $\Theta(\log_{\min}(r,N) \cdot N)$ is clearly optimal for $r = \Omega(N)$. For primitives of rank at least three that are self-resettable, we have presented a $\Theta(\log N/\log \log N)$ algorithm, which
gives an asymptotic improvement in RMR time complexity for primitives of rank $o(\log N)$. This algorithm is
time-optimal for certain self-resettable primitives of constant rank. In designing these algorithms, our main
goal was to achieve certain asymptotic time complexities. In particular, we have not concerned ourselves with
designing algorithms that can be practically applied. Indeed, it is difficult to design practical algorithms when
assuming so little of the $fetch-and-$ primitives being used. It is likely that by exploiting the semantics of a
particular primitive, our algorithms could be optimized considerably.

We believe that the notion of rank defined in this paper may be a suitable way of characterizing the “power”
of primitives from the standpoint of blocking synchronization, much like the notion of a consensus number,
which is used in Herlihy’s wait-free hierarchy [5], reflects the “power” of primitives from the standpoint of
nonblocking synchronization. Interestingly, primitives like compare-and-swap that are considered to be powerful
according to Herlihy’s hierarchy are weak from a blocking synchronization standpoint (since they are subject
to our $\Omega(\log N / \log \log N)$ lower bound [1]). Also, primitives like fetch-and-increment and fetch-and-store that
are considered to be powerful from a blocking synchronization standpoint are considered quite weak according
to Herlihy’s hierarchy. (They have consensus number two.) This difference arises because in nonblocking
algorithms, the need to reach consensus is fundamental (as shown by Herlihy), while in blocking algorithms, the
need to order competing processes is important.

The $\Theta(\log N / \log \log N)$ algorithm in Sec. 4 shows that $\Omega(\log N / \log \log N)$ is a tight lower bound for some
class of synchronization primitives. Unfortunately, we have been unable to adapt the algorithm to work with
only reads, writes, and comparison primitives. Currently, we still believe that $\Omega(\log N)$ is a tight lower bound
for algorithms based on such operations, as conjectured by us earlier [1]. Our $\Theta(\log N / \log \log N)$ algorithm
may shed some light on this issue. In particular, it shows that a better bound must necessarily be based on
proof techniques that exclude some of the primitives allowed by the current proof.
